Homework 2: Evaluating Randomized Experiments

Neeraj Sharma

05/02/2020

- 1. Estimate the treatment effect and the associated standard error on the raw data given to you, assuming there are no mistakes in or problems with the data.
- 2. It's always a good idea to check a data set for errors. Clean this data set as you think appropriate. As an answer to this question, note all the kinds of changes you made to the data, a few words explaining your reason for the change, and which observations you changed (noting the observation number included as a variable in the data set for identification purposes). If it is totally obvious which observations you changed and there are a large number in the category (e.g. if you decided to drop all White study participants), you can just note what you did for that change ("I dropped all white participants") and explain why.
- 3. With your cleaned data set, re-estimate the treatment effect and estimated standard error, assuming the randomization worked fine.
- 4. Evaluate whether the randomization appears legitimate. If you don't think the randomization is legitimate, what is your evidence? (Hint: something went wrong.)
- 5. Offer your best hypothesis/hypotheses as to what went wrong with the randomization? What evidence do you have to support your hypothesis(es)? For each of these hypotheses, describe your best strategy for estimating a plausible treatment effect, in spite of the bad randomization. (But don't actually estimate that treatment effect.)
- 6. Given your answer to question five come up with your best estimate of the true treatment effect in the experiment as well as its standard error.

In 1 and 3, assume randomization worked. For the rest, then you can't assume randomization worked. How to estimate if it's random. Multiple linear regression isn't awesome for prediction but we should use it here for randomness assessment.

Multiple Linear Regression Example

fit <- lm(y ~ x1 + x2 + x3, data=mydata) summary (fit) # show results anova function can be used to compare different linear models

Question 1: Estimate the treatment effect and the associated standard error on the raw data given to you, assuming there are no mistakes in or problems with the data.

It is impossible to analyze the outcome of an individual with treatment and without treatment because each individual can only be slotted into one category.

```
# Read in the raw data.
raw <- read_csv("problem_set2.csv")</pre>
## Parsed with column specification:
## cols(
##
     subject_id = col_double(),
     hours = col_double(),
##
##
     treatment = col_double(),
##
     community_center = col_character(),
     female = col_character(),
##
     age = col double(),
##
##
     bmi = col_double(),
```

```
education = col_character(),
    race_ethnicity = col_character()
##
## )
raw %>%
  group_by(treatment) %>%
 summarize all(mean)
## Warning in mean.default(community_center): argument is not numeric or

                                              NA
                                                     NA
                                                         24.7 29.0
                                                                            NA
             1
                     484. 27.5
                                              NA
                                                     NA 25.2 27.1
                                                                            NA
## # ... with 1 more variable: race_ethnicity <dbl>
# T test
# Fails because female in the raw file is not all uniform.
# t.test(raw$hours ~ raw$female)
# t.test(data$hours ~ data$female)
# mean(data$bmi)
# sd(data$bmi)/sqrt(length(data$bmi))
# broom::tidy(aov(bmi ~ treatment, data))
```

How to tell if you aren't random. Clues that it is the case is done through a balance table. Compare means of each observable metric between treatment and control groups. You do a t-test to compare them. THIS IS NOT GREAT, but still do it to confirm you are balanced on your observables.

```
"0", female)))) %>%
  # Encode education variable to be a factor
  mutate(education = factor(education, levels = c("less than high school",
                                                  "high school",
                                                   "higher degree"))) %>%
  # Fix all BLACK observations to normal capitalization structure.
  mutate(race_ethnicity = str_to_sentence(race_ethnicity),
         race_ethnicity = factor(race_ethnicity, c("Black", "Hispanic", "White"))) %>%
  # -99 is missing age data so I reincode it at missing age data. https://cran.r-project.org/web/packag
  mutate(age = na_if(age, -99)) %>%
  # Fixing messed up hours readings. They start at 60 and upwards and that's 1 hr so I fix based on tha
  mutate(hours = if_else(hours >= 60, hours / 60, hours)) %>%
  # Currently I have removed improper values, but I could also justify multiplying by 10.
 mutate(bmi = ifelse(bmi < 1, NA, bmi))</pre>
# Checking randomization
# Balance Table
data %>%

  labs(x = "Hours", y = "Count", title = "Histogram of distribution of Hours between groups") +
  theme_economist() +
  facet_wrap(~ treatment)
```

It is clear that there are numerous outlines in terms of BMI data. Given that a BMI of less than 18.5 is underweight, having a BMI of ~1 is underweight to the point of imposibility. Thus, I believe these data points were improperly encoded and given the distribution, they appear to have simply misplaced the decimal point two places to the left.

##Question 4:Evaluate whether the randomization appears legitimate. If you don't think the randomization is legitimate, what is your evidence? (Hint: something went wrong.)

If there was perfect random assignment, you could randomly pluck 100 people, then pluck 100 more, their distributions should be the same of age BMI Community etc. Systematic differences imply that it's not random. Talk about mean median and stuff but you don't need to do a t-test.

```
treatment_bmi <- glm(treatment ~ bmi, data = data, family = binomial)
summary(treatment_bmi)</pre>
```

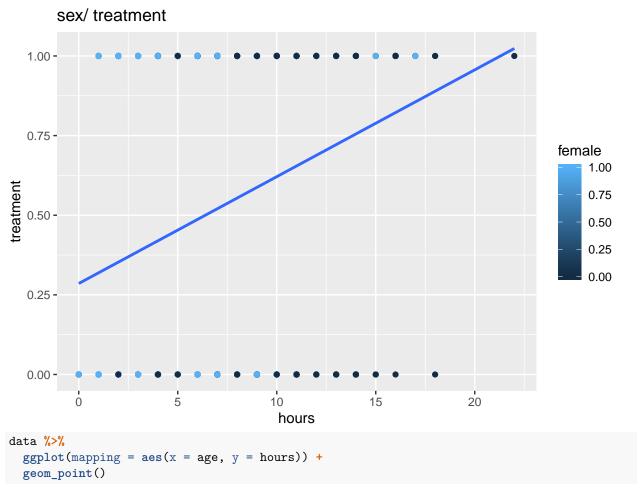

```
